Finding Accurate Frontiers:
A Knowledge-Intensive Approach to Relational Learning

Abstract
An approach to analytic learning is described that searches for accurate entailments of a Horn Clause domain
theory. A hill-climbing search, guided by an information
based evaluation function, is performed by applying a set
of operators that derive frontiers from domain theories.
The analytic learning system is one component of a
multi-strategy relational learning system. We compare
the accuracy of concepts learned with this analytic
strategy to concepts learned with an analytic strategy that
operationalizes the domain theory.

Introduction
There are two general approaches to learning classification
rules. Empirical learning programs operate by finding
regularities among a group of training examples. Analytic
learning systems use a domain theory to explain the
classification of examples, and form a general description
of the class of examples with the same explanation. In
this paper, we discuss an approach to learning classification
rules that integrates empirical and analytic learning methods. The goal of this integration is to create
concept descriptions that are more accurate classifiers than
both the original domain theory (which serves as input to
the analytic learning component) and the rules that would
arise if only the empirical learning component were used.
We describe a new analytic learning method that returns a
frontier (i.e., conjunctions and disjunctions of operational
and non-operational literals) instead of an
operationalization (i.e., a conjunction of operational
literals learned empirically. In general FOCL learns clauses
that cover some positive and no negative examples. FOIL starts
to learn a clause body by finding the literal with the
maximum information gain, and continues to add literals
to the clause body until the clause does not cover any
negative examples. After learning each clause, FOIL removes
from further consideration the positive examples
covered by that clause. The learning process ends when all
positive examples have been covered by some clause.

FOIL
FOIL learns classification rules by constructing a set of
Horn Clauses in terms of known operational predicates.
Each clause body consists of a conjunction of literals that
cover some positive and no negative examples. FOIL starts
to learn a clause body by finding the literal with the
maximum information gain, and continues to add literals
to the clause body until the clause does not cover any
negative examples. After learning each clause, FOIL removes
from further consideration the positive examples
covered by that clause. The learning process ends when all
positive examples have been covered by some clause.

FOCL
FOCL extends FOIL by incorporating a compatible EBL
component. This allows FOCL to take advantage of an
initial domain theory. When constructing a clause body,
there are two ways that FOCL can add literals. First, it can
create literals via the same empirical method used by FOIL.
Second, it can create literals by operationalizing a target
candidate, i.e., a non-operational definition of the concept to
be learned (Mitchell, et al., 1986). FOCL uses FOIL's
information-based evaluation function to determine whether
to add a literal learned empirically or a conjunction of
literals learned analytically. In general FOCL learns clauses
of the form \( x \leftarrow O_d \wedge O_e \) where \( O_d \) is an initial
conjunction of operational literals learned empirically, \( O_d \) is a conjunction of literals found by operationalizing the
domain theory, and \( O_e \) is a final conjunction of literals
learned empirically. Pazzani, et al. (1991) demonstrate

1. We use domain theory to refer to a set of Horn-Clause rules
given to a learner as an approximate definition of a concept
and learned concept to refer to the result of learning.
2. We use the term operational to refer to predicates that are
defined extensionally (i.e., defined by a collection of facts).
However, the results apply to any satisfier determined
definition of operationality.
3. Note the target concept is operationalized at most once per
clause and that either \( O_d, O_d, \text{ or } O_e \) may be empty.
that FOCL can utilize incomplete and incorrect domain theories. We attribute this capability to its uniform use of an evaluation function to decide whether to include literals learned empirically or analytically.

Operationalization in FOCL differs from that of most EBL programs in that it uses a set of positive and negative examples, rather than a single positive example. A non-operational literal is operationalized by producing a specialization of a domain theory that is a conjunction of operational literals. When there are several ways of operationalizing a literal (i.e., there are multiple, disjunctive clauses), the information gain metric is used to determine which clause should be used by computing the number of examples covered by each clause. Figure 1 displays a typical domain theory with an operationalization \((f\text{AgAhAkALApAq})\) represented as bold nodes.

**Figure 1.** The bold nodes represent one operationalization \((f\text{AgAhAkALApAq})\) of the domain theory. In standard EBL, this path would be chosen if it were a proof of a single positive example. In FOCL, this path would be taken if the choice made at a disjunctive node had greater information gain (with respect to a set of positive and negative examples) than alternative choices.

**Operationalization**

The operationalization process yields a specialization of the target concept. Indeed, several systems designed to deal with overly general theories rely on the operationalization process to specialize domain theories (Flann & Dietterich, 1990; Cohen, 1992). However, fully operationalizing a domain theory can result in several problems:

1. Overspecialization of correct non-operational concepts. For example, if the domain theory in Figure 1 is completely correct, then a correct operational definition will consist of eight clauses. However, if there are few examples, or some combinations of operationalizations are rare, then there may not be a positive example corresponding to all combinations of all operationalizations of non-operational predicates. As a consequence, the learned concept may not include some combinations of operational predicates (e.g., \(\text{lAjAkalA拉萨})\), although there is no evidence that these specializations are incorrect.

2. Replication of empirical learning. If there is a literal omitted from a clause of a non-operational predicate, then this literal will be omitted from each operationalization involving this predicate. For example, if the domain theory in Figure 1 erroneously contained the rule \(b\leftrightarrow\text{fAh}\) instead of \(b\leftrightarrow\text{fAgAh}\), then each operationalization of the target concept using this predicate (i.e., \(\text{fAhAkalA拉萨}, \text{fAhAkalAApAq}, \text{and fAhAkalA拉萨b})\) will contain the same omission. FOCL can recover from this error if its empirical component can find the omitted literal, \(g\). However, to obtain a correct learned concept description, FOCL would have to find the same condition independently three times on three different sets of examples. This replication of empirical learning is analogous to the replicated subtree problem in decision trees (Pagallo & Haussler, 1990). This problem should be most noticeable when there are few training examples. Under this circumstance, it is unlikely that empirical learning on several arbitrary partitions of a data set will be as accurate as learning from the larger data set.

3. Proofs involving incorrect non-operational predicates may be ignored. If the definition of a non-operational predicate (e.g., \(c\) in Figure 1) is not true of any positive example, then the analytic learner will not return any operationalization using this predicate. This reduces the usefulness of the domain theory for an analytic learner. For example, if \(c\) is not true of any positive example, then FOCL as previously described can find only two operationalizations: \(UAV\) and \(WAX\). Again, we anticipate that this problem will be most severe when there are few training examples. With many examples, the empirical learner can produce accurate clauses that mitigate this problem.

**Figure 2.** The bold nodes represent one frontier of the domain theory, \(\text{bA (f\text{MAAO) v (Paq}})\).

**Frontiers of a Domain Theory**

To address the problems raised in the previous section, we propose an analytic learner that does not necessarily fully operationalize target concepts. Instead, the learner returns a frontier of the domain theory. A frontier differs from an operationalization of a domain theory in three ways. The frontier represented by those nodes immediately above the line in Figure 2, \(\text{bA (f\text{MAAO) v (Paq}})\), illustrates these differences:

1. Non-operational predicates (e.g., \(b\)) can appear in the frontier.
2. A disjunction of two or more clauses that define a non-operational predicate (e.g., \( \forall (p \land q) \)) can appear in the frontier.

3. A frontier does not necessarily include all literals in a conjunction (e.g., neither \( \forall \) nor any specialization of \( \forall \) appears in the frontier).

Combined, the first two distinguishing features of a frontier address the first two problems associated with operationalization. Overspecialization of correct non-operational concepts can be avoided if the analytic component returns a more general concept description. Similarly, replication of empirical learning can be avoided if the analytic component returns a frontier more general than an operationalization. For example, if the domain theory in Figure 2 erroneously contained the rule \( b \leftarrow \forall a \)ahkakal \( d \) was returned, then an empirical learner would only need to be invoked once to specialize this conjunction by adding \( \forall \). Of course, if one of the clauses defining \( d \) were incorrect, it would make sense to specialize \( d \). However, operationalization is not the only means of specialization. For example, if the analytic learner returned \( \forall a \)ahkakal (\( \forall (p \land q) \)), then replication of induction problem could also be avoided. This would be desirable if the clause \( \forall a \leftarrow b \) were incorrect.

The third problem with operationalization can be addressed by removing some literals from a conjunction. For example, if no positive examples use \( a \leftarrow b \)acad because \( c \) is not true of any positive example, then the analytic learner might want to consider ignoring \( c \) and trying \( a \leftarrow b \)ad. This would allow potentially useful parts of the domain theory (e.g. \( b \) and \( d \)) to be used by the analytic learner, even though they may be conjoined with incorrect parts.

The notion of a frontier has been used before in analytic learning. However, the previous work has assumed that the domain theory is correct and has focused on increasing the utility of learned concepts (Hirsh, 1988; Keller, 1988; Segre, 1987) or learning from intractable domain theories (Braverman & Russell, 1988). Here, we do not assume that the domain theory is correct.

We argue that to increase the accuracy of learned concepts, an analytic learner should have the ability to select the generality of a frontier derived from a domain theory. To validate our hypothesis, we will replace the operationalization procedure in FOCL with an analytic learner that returns a frontier. In order to avoid confusion with FOCL, we use the name FOCL-FRONTIER to refer to the system that combines this new analytic learner with an empirical learning component based on FOIL. In general, FOCL-FRONTIER learns clauses of the form \( x \leftarrow O_1 \land F_d \land O_f \) where \( O_j \) is an initial conjunction of operational literals learned empirically, \( F_d \) is a frontier of the domain theory, and \( O_f \) is a final conjunction of literals learned empirically. We anticipate that due to its use of a frontier rather than an operationalization, FOCL-FRONTIER will be more accurate than FOCL, particularly when there are few training examples or the domain theory is very accurate.

Enumerating Frontiers of a Domain Theory

Formally, a frontier can be defined as follows. Let \( b \) represent a conjunction of literals and \( p \) represent a single literal.

1. The target concept is a frontier.

2. A new frontier can be formed from an existing frontier by replacing a literal \( p \) with \( b_1 \lor \ldots \lor b_n \) provided there are rules \( d \leftarrow b_1, \ldots, d \leftarrow b_n \). 

3. A new frontier can be formed from an existing frontier by replacing a disjunction \( b_1 \lor \ldots \lor b_n \) with \( b_1 \lor \ldots \lor b_{i+1} \lor \ldots \lor b_n \) for any \( i \). This deletes \( b_i \).

4. A new frontier can be formed from an existing frontier by replacing a conjunction \( p_1 \land \ldots \land p_i \land p_{i+1} \land \ldots \land p_n \) with \( p_1 \land \ldots \land p_{i-1} \land p_{i+1} \land \ldots \land p_n \) for any \( i \). This deletes \( p_i \).

One approach to analytic learning would be to enumerate all possible frontiers. The information gain of each frontier could be computed, and if the frontier with the maximum information gain has greater information gain than any literal found empirically, then this frontier would be added to the clause under construction. Such an approach would be impractical for all but the most trivial, non-recursive domain theories. Since each frontier specifies a unique combination of leaf nodes of an and-or tree (i.e., selecting all leaves of a subtree is equivalent to selecting the root of the subtree and selecting no leaves of a subtree is equivalent to deleting the root of a subtree), there are \( 2^k \) frontiers of a domain theory that has \( k \) nodes in the and/or tree. For example, if every non-operational predicate has \( n \) clauses, each clause is a conjunction of \( m \) literals, and inference chains have a depth of \( d \) and-nodes, then the number of frontiers is \( 2^md^d \).

Deriving Frontiers from the Target Concept

Due to the intractability of enumerating all possible frontiers, we propose a heuristic approach based upon hill-climbing search. The frontier is initialized to the target concept. A set of transformation operators is applied to the current frontier to create a set of possible frontiers. If none of the possible frontiers has information gain greater than that of the current frontier, then the current frontier is returned. Otherwise, the potential frontier with the maximum information gain becomes the current frontier and the process of applying transformation operators is repeated. The following transformation operators are used:

- **Clause specialization:**
  If there is a frontier containing a literal \( p \), and there are exactly \( n \) rules of the form \( p \leftrightarrow b_1, \ldots, p \leftrightarrow b_n \), then \( n \) frontiers formed by replacing \( p \) with \( b_i \) are evaluated.

4. The information gain of a frontier is calculated in the same manner than Quinlan (1990) calculates the information gain of a literal: by counting the number of positive and negative examples that meet the conditions represented by the frontier.

5. The numeric restrictions placed upon the applicability of each operator are for efficiency reasons (i.e., to ensure that each unique frontier is evaluated only once).
• **Specialization by removing disjunctions:**
  a. If there is a frontier containing a literal \( p \), and there are \( n \) rules of the form \( p \leftarrow b_1, ..., p \leftarrow b_n, p \leftarrow b_m \), then \( n \) frontiers formed by replacing \( p \) with \( b_1 \lor b_2 \lor ... \lor b_m \) are evaluated (provided \( n > 2 \)).
  b. If there is a frontier containing a disjunction \( b_1 \lor b_2 \lor ... \lor b_m \), then \( m \) frontiers replacing this disjunction with \( b_1 \lor b_2 \lor ... \lor b_m \) are evaluated (provided \( m > 2 \)).

• **Generalization by adding disjunctions:**
  If there is a frontier containing a (possibly trivial) disjunction of conjunction of literals \( b_1 \lor b_2 \lor ... \lor b_m \), and there are rules of the form \( p \leftarrow b_1, ..., p \leftarrow b_n, p \leftarrow b_1, ..., p \leftarrow b_n \), and \( m < n-1 \), then \( n - m \) frontiers replacing the disjunction \( b_1 \lor b_2 \lor ... \lor b_m \) with \( b_1 \lor b_2 \lor ... \lor b_m \) are evaluated. This is implemented efficiently by keeping a derivation of each frontier, rather than by searching for frontiers matching this pattern.

• **Generalization by literal deletion:**
  If there is a frontier containing a conjunction of literals \( p_1 \land p_2 \land ... \land p_n \), then \( n \) frontiers replacing this conjunction with \( p_1 \land p_2 \land ... \land p_n \) are evaluated.

There is a close correspondence between the recursive definition of a frontier and these transformation operators. However, there is not a one-to-one correspondence because we have found empirically that in some situations it is advantageous to build a disjunction by adding disjunctions and in other cases it is advantageous to build a disjunction by removing disjunctions. The former tends to occur when few clauses of a predicate are correct while the latter tends to occur when few clauses are incorrect.

Note that the first three frontier operators derive logical entailments from the domain theory while the last does not. Deleting literals from a conjunction is a means of finding an abductive hypothesis. For example, in EITHER (Ourston & Mooney, 1990), a literal can be assumed to be true during the proof process of a single example. One difference between FOCL-FRONTIER and the abduction process of EITHER is that EITHER considers all likely assumptions for each unexplained positive example, and FOCL-FRONTIER uses a greedy approach to deletion based on an evaluation of the effect on a set of examples.

**Evaluation**

In this section, we report on a series of experiments in which we compare FOCL using empirical learning alone (EMPIRICAL), FOCL using a combination of empirical learning and operationalization, and FOCL-FRONTIER. We evaluate the performance of each algorithm in several domains. The goal of these experiments is to substantiate the claim that analytic learning via frontier transformations results in more accurate learned concept descriptions than analytic learning via operationalization. Throughout this paper, we use an analysis of variance to determine if the difference in accuracy between algorithms is significant.

![Figure 3. A comparison of FOCL's empirical component (EMPIRICAL), FOCL using both empirical learning and operationalization, and FOCL-FRONTIER in the chess end gain domain. Upper: The accuracy of EMPIRICAL (given training sets of size 50 and 200) and the average accuracy of the initial theory as a function of the number of changes to the domain theory. Lower: The accuracy of FOCL and FOCL-FRONTIER on the same data.](image-url)
curves for 50 and 200 training examples are presented. Figure 3 (upper) graphs the accuracy of the initial theory and the concept description learned by FOCL's empirical component as functions of the number of modifications to the correct domain theory. Figure 3 (lower) graphs the accuracy of FOCL and FOCL-FRONTIER.

The following conclusions may be drawn from these experiments. First, FOCL-FRONTIER is more accurate than FOCL when there are few training examples. An analysis of variance indicates that the analytic learning algorithm has a significant effect on the accuracy (p<.0001) when there are 25, 50 and 75 training examples. However, where there are 150 or 200 training examples, there is no significant difference in accuracy between the analytic learning algorithms (as well as the empirical algorithm) are very accurate on this problem with larger numbers of training examples. Second, the difference in accuracy between FOCL and FOCL-FRONTIER is greatest when the domain theory has few errors. With 25 and 50 examples, there is a significant interaction between the number of modifications to the domain theory and the algorithm (p<.0001 and p<.005, respectively).

During these experiments, we also recorded the amount of work EMPIRICAL, FOCL, and FOCL-FRONTIER performed while learning a concept description. Pazzani and Kibler (1990) argue that the number of times information gain is computed is a good metric for describing the size of the search space explored by FOCL. Figure 4 graphs these data as a function of the number of modifications to the domain theory and the algorithm (p<.0001 and p<.005, respectively).

Educational Loans

The second problem studied involves determining if a student is required to pay back a loan based on enrollment and employment information. This theory was constructed by an honors student who had experience processing loans. This problem, available from the UC Irvine repository, was previously used by an extension to FOCL that revises domain theories (Pazzani & Brunk, 1991). The domain theory is 76.8% accurate on a set of 1000 examples.

We ran 16 trials of FOCL and FOCL-FRONTIER with this domain theory on randomly selected training sets ranging from 10 to 100 examples and measured the accuracy of the learned concept by testing on 200 distinct test examples. The results indicate that the learning algorithm has a significant effect on the accuracy of the learned concept (p<.0001). Figure 5 plots the mean accuracy of the three algorithms as a function of the number of training examples.

Figure 5. The accuracy of FOCL's empirical component alone, FOCL with operationalization and FOCL-FRONTIER on the student loan data.

Nynex Max

Nynex Max (Rabinowitz, et al., 1991) is an expert system that is used by NYNEX (the parent company of New York Telephone and New England Telephone) at several sites to determine the location of a malfunction for customer-reported telephone troubles. It can be viewed as solving a
classification problem where the input is data such as the
type of switching equipment, various voltages and
resistances and the output is the location to which a
repairman should be dispatched (e.g., the problem is in the
customer’s equipment, the customer’s wiring, the cable
facilities, or the central office). Nynex Max requires some
customization at each site in which it is installed.

In this experiment, we compare the effectiveness of
FOCL-FRONTIER and FOCL at customizing the Nynex Max
knowledge-base. The initial domain theory is taken from
one site, and the training data is the desired output of
Nynex Max at a different site. Figure 6 shows the
accuracy of the learning algorithms at
customizing the Max knowledge-base.

Figure 6. The accuracy of the learning algorithms at
customizing the Max knowledge-base.

In this experiment, we compare the effectiveness of
FOCL-FRONTIER and FOCL at customizing the Nynex Max
knowledge-base. The initial domain theory is taken from
one site, and the training data is the desired output of
Nynex Max at a different site. Figure 6 shows the
accuracy of the learning algorithms (as measured on 200
independent test examples), averaged over 10 runs as a
function of the number of training examples.

FOCL-FRONTIER is more accurate than FOCL (p<.0001).
This occurs because the initial domain theory is fairly large
(about 75 rules), very disjunctive, and fairly accurate (about
95.4%). Under these circumstances, FOCL requires many
events to form many operational rules, while
FOCL-FRONTIER learns fewer, more general rules.
FoCL-FRONTIER is the only algorithm to achieve an
accuracy significantly higher than the initial domain
theory.

Related Work

Cohen (1990; 1991a) describes the ELGIN systems
that makes use of background knowledge in a way similar to
FOCL-FRONTIER. In particular, one variant of ELGIN
called ANA-EBL, finds concepts in which all but k nodes of
a proof tree are operational. The algorithm, which is
exponential in k, learns more accurate rules from overly
general domain theories than an algorithm that uses only
operational predicates. A different variant of ELGIN, called
K-TIPS, selects k nodes of a proof tree and returns the most
general nodes in the proof tree that are not ancestors of the
selected nodes. This enables the system to learn a set of
clauses containing at most k literals from the proof tree.
Some of the literals may be non-operational and some
subtrees may be deleted from the proof tree. In some
ways, ELGIN is like the optimal algorithm we described
above that enumerates all possible frontiers. A major
difference is that ELGIN does not allow disjunction in
proofs, and for efficiency reasons is restricted to using
small values of k. FOCL-FRONTIER is not restricted in
such a fashion, since it relies on hill-climbing search to
avoid enumerating all possible hypotheses. In addition,
the empirical learning component of FOCL-FRONTIER
allows it to learn from overly specific domain theories in
addition to overly general domain theories.

In the GRENDEL system, Cohen (1991b) uses a
grammar rather than a domain theory to generate
hypotheses. Cohen shows that this grammar provides an
elegant way to describe the hypothesis space searched by
FOCL. It is possible to encode the domain theory in such a
grammar. In addition, it is possible to encode the
hypothesis space searched by FOCL in the grammar.
GRENDEL uses a hill-climbing search method similar to
the operationalization process in FOCL to determine which
hypothesis to derive from the grammar. Cohen (1991b)
shows that augmenting GRENDEL with advice to prefer
grammar rules corresponding to the domain theory results
in concepts that are as accurate as those of FOCL (with
operationalization) on the chess end game problem. The
primary difference between GRENDEL and FOCL-FRONTIER
is that FOCL-FRONTIER contains operators for deleting
literals from and-nodes and for incorporating several
disjunctions from or-nodes. However, due to the generality
of GRENDEL’s grammatical approach, it should be possible
to extend GRENDEL by writing a preprocessor that converts
a domain theory into a grammar that simulate these
operators. Here, we have shown that these operators result
in increased accuracy, so it is likely that a grammar based
on the operators proposed here would increase GRENDEL’s
accuracy.

FOCL-FRONTIER is in some ways similar to theory
revision systems, like EITHER (Ourston & Mooney, 1990).
However, theory revision systems have an additional goal
of making minimal revisions to a theory, while
FOCL-FRONTIER uses a set of frontiers from the domain
theory (and/or empirical learning) to discriminate positive
from negative examples. EITHER deals with propositional
theories and would not be able to revise any of the
relational theories used in the experiments here. A more
recent theory revision system, FORTE (Richards & Mooney,
1991), is capable of revising relational theories. It has
been tested on one problem on which we have run FOCL,
the illegal chess problem from Pazzani & Kibler (1992).
Richards (1992) reports that with 100 training examples
FOCL is significantly more accurate than FORTE (97.9%
and 95.6% respectively). For this problem,
FOCL-FRONTIER is 98.5% accurate (averaged over 20
trials). FORTE has a problem with this domain, since it
contains two overly-general clauses for the same relation
and its revision operators assume that at most one clause is
overly general. Although it is not possible to draw a
general conclusion from this single example, it does
indicate that there are techniques for taking advantage of
information contained in a theory that FOCL utilizes that
are not incorporated into FORTE.
Future Work

Here, we have described one set of general purpose operators that derive frontiers. We are currently experimenting with more special purpose operators designed to handle commonly occurring problems in knowledge-based systems. For example, one might wish to consider operators that negate a literal in a frontier (since we occasionally omit a not from rules) or that change the order of arguments to a predicate. Initial experiments (Pazzani, 1992) with one such operator in FOCL (replacing one predicate with a related predicate) yielded promising results.

Conclusion

In this paper, we have presented an approach to integrating empirical and analytic learning that differs from previous approaches in that it uses an information theoretic metric on a set of training examples to determine the generality of the concepts derived from the domain theory. Although it is possible that the hill-climbing search algorithm will find a local maximum, experimentally we have demonstrated that in situations where there are few training examples, the domain theory is very accurate, or the domain theory is highly disjunctive this approach learns more accurate concept descriptions than either empirical learning alone or a similar approach that integrates empirical learning and operationalization. From this we conclude that there is an advantage in allowing the analytic learner to select the generality of a frontier derived from a domain theory both in terms of accuracy and in terms of the amount of work required to learn a concept description.
