Abstract

One of the goals of a cooperative game is to compute a value division to the players from which they have no incentive to deviate. This concept is formalized as the notion of the core. To obtain a value division that motivates players to cooperate to a greater extent or that is more robust under noise, the notions of the strong least core and the weak least core have been considered. In this paper, we characterize the strong and the weak least cores of supermodular cooperative games using the theory of minimizing crossing submodular functions. We then apply our characterizations to two representative supermodular cooperative games, namely, the induced subgraph game generalized to hypergraphs and the airport game. For these games, we derive explicit forms of the strong and weak least core values, and provide polynomial-time algorithms that compute value divisions in the strong and weak least cores.

Introduction

Cooperation and the sharing of resources are crucial factors in achieving a sustainable and resilient economy. Based on these concepts, services such as vehicle sharing, office sharing, house sharing, and skill sharing (Reisch and Thgersen 2015) can be realized. Individuals can reduce their own costs by dividing the cost of services with other customers, instead of using these services alone. A crucial challenge in such scenarios is to divide the cost so that all customers are satisfied with the division and are motivated to cooperate.

In this paper, we tackle this problem from the game-theoretic perspective of cooperative games. We explain the motivation underlying cooperative games using the example of sharing taxis. The total fare for a group of customers taking a taxi is typically determined by the customer who travels farthest in the group. Our task is to divide the total fare among these customers. However, if some customers can pay less by forming a smaller group and dividing the total fare of the subgroup appropriately, they will leave the larger group. Hence, we need to find a stable division that avoids such a deviation. This concept have been formalized as the notion of the core (Gillies 1959).

It is known that the core exists for the taxi example. More generally, there is a core within supermodular cooperative games (sometimes called convex cooperative games), that is, cooperative games with supermodular utility functions (Shapley 1971). Indeed, a value division called the Shapley value (Shapley 1967) is always in the core.

It is natural to consider what is the “stablest” value division, rather than simply any stable value division. One reason is to motivate the players of the game to cooperate to the greatest extent. From the perspective of a manager of the game, this extent can be regarded as the tax that can be imposed on players while still ensuring they play the game. Of course, the manager aims to maximize the tax. A second reason to identify the stablest value division is to enhance robustness to noise. In practice, we cannot accurately measure the valuation of each group because of external noise. In such a case, the loss incurred when a group deviates (with respect to the observed valuations) should be regarded as the safety margin for the group not to deviate (Li and Conitzer 2015). To address these issues, several extensions of the core have been considered. Two well-known examples are the strong least core and the weak least core (Shapley and Shubik 1966). Indeed, it is known that value divisions in these cores are most robust against a certain type of noise (Li and Conitzer 2015).

In this paper, we consider computational aspects of the strong and weak least cores. First, we provide theoretical characterizations of those cores of supermodular cooperative games using the theory of minimizing crossing submodular functions. To see that our characterizations are useful to interpret those cores and design efficient algorithms for computing a value division in them, we analyze two representative supermodular cooperative games, namely, the induced subgraph game (Deng and Papadimitriou 1994) generalized to hypergraphs and the airport game (Littlechild and Owen 1973). The induced subgraph game models the profit among countries from forming alliances, whereas the airport game can model the sharing of a runway at an airport and the sharing of taxis. To the best of our knowledge, there has been no computational analysis of the weak least core, and the difference between the strong and weak least cores has not been discussed. We emphasize that we obtain the strong and weak least core values in a uniform manner, which helps us to analyze the difference between them.
Related Work

Supermodular games are a well-studied class of cooperative games. Examples include the induced subgraph game (Deng and Papadimitriou 1994), airport game (Lillicleand and Owen 1973), public good game (Oishi and Nakayama 2009), bidder collusion game (Graham, Marshall, and Richard 1990), multicast tree game (Feigenbaum, Papadimitriou, and Shenker 2001), and bankruptcy game (O’Neill 1982). Our characterizations of the strong and weak least core values can be applied to each of these.

Algorithms for computing the strong least core value have already been developed (Kuipers 1996; Faigle, Kern, and Kuipers 2001). However, as these algorithms solve optimization problems on the extended polymatroid associated with a crossing submodular function, we suspect that they are essentially impractical. In contrast, we have characterized the strong and weak least cores, and used these characterizations to obtain efficient algorithms that compute the strong and weak least core values for specific games.

When defining the strong and weak least cores, we strengthened the stability constraint \( x(S) \geq \nu(S) \) in the definition of the core. An alternative approach is to replace the constraint \( x(V) = \nu(V) + \epsilon \) (see the formal definition of the core in the next section). The minimum \( \epsilon \) that renders the program feasible is called the cost of stability (Bachrach et al. 2009). This corresponds to having a benevolent external party that wishes to stabilize the game by offering subsidies to players if they remain in the grand coalition. The cost of stability focuses on the case where the core is empty, and the cost of stability of a supermodular game is always zero. Hence, the cost of stability is inappropriate for defining the stistlest value division.

Cooperative games represented by marginal contribution nets (Jeong and Shoham 2005) can be seen as a generalization of the induced subgraph game for which negative weights are allowed. Although (Hirayama et al. 2014) considered computing the least cores in this general setting, the time complexity of their algorithm is exponential.

Preliminaries

For an integer \( k \), we denote the set \( \{1, 2, \ldots, k\} \) as \([k]\). The set of non-negative real values is denoted by \( \mathbb{R}_+ \). We use bold symbols such as \( \mathbf{x} \) to denote vectors. Let \( V \) be a finite set. For a vector \( \mathbf{x} \in \mathbb{R}^V \) and a set \( S \subseteq V \), we denote the value \( \sum_{v \in S} x(v) \) as \( x(S) \).

A function \( f : 2^V \to \mathbb{R} \) is called submodular (resp., supermodular) if

\[
\begin{align*}
\forall S, T \subseteq V, \quad f(S) + f(T) &\geq f(S \cap T) + f(S \cup T) \\
(\text{resp.,} \quad f(S) + f(T) &\leq f(S \cap T) + f(S \cup T))
\end{align*}
\]

for all \( S, T \subseteq V \).

We say that two sets \( S, T \subseteq V \) are crossing if \( S \cap T \neq \emptyset, S \setminus T \neq \emptyset, T \setminus S \neq \emptyset, \) and \( S \cup T \neq V \). A function \( f : 2^V \to \mathbb{R} \) is called crossing submodular (Fujishige 2005) if

\[
\begin{align*}
\forall S, T \subseteq V, \quad f(S) + f(T) &\geq f(S \cap T) + f(S \cup T)
\end{align*}
\]

holds for any crossing \( S, T \subseteq V \).

We say that a family of sets \( S \) is a copartition of \( V \) if \( \{V \setminus S \mid S \in \mathcal{S}\} \) is a partition of \( V \). For an integer \( k \), let \( \mathcal{P}_k(V) \) (resp., \( \mathcal{P}_k(V) \)) be the family of all partitions (resp., copartitions) \( S \) of \( V \) into at least \( k \) sets, such that each set \( S \in \mathcal{S} \) is nontrivial, that is, \( \emptyset \nsubseteq S \nsubseteq V \).

Cooperative Games

We now briefly describe the framework of cooperative games. For more details, readers are referred to (Chalkiadakis, Elkind, and Wooldridge 2011) and the references therein. A cooperative game is a pair \( (V, \nu) \), where \( V \) is a set of players and \( \nu : 2^V \to \mathbb{R}_+ \) is a function called the characteristic function. We can regard \( \nu(S) \) as the profit when the players in \( S \) form a coalition. We always assume that \( \nu(\emptyset) = 0 \). We say that \( x \in \mathbb{R}^V \) is a value division if \( x(V) = \nu(V) \), that is, a value division is a distribution of the total profit to the players.

Suppose that a value division \( x \in \mathbb{R}^V \) satisfies \( x(S) < \nu(S) \) for some \( S \subseteq V \). In such a case, the players in \( S \) will form a coalition and leave \( V \). We say that a value division is in the core if such an \( S \) does not exist. More formally, a value division \( x \in \mathbb{R}^V \) is in the core if \( x(S) \geq \nu(S) \) for all \( S \subseteq V \).

We say that a cooperative game \( (V, \nu) \) is a supermodular (cooperative) game if \( \nu \) is supermodular. It is known that the core of a supermodular game is nonempty; in particular, a value division called the Shapley value is always in the core (Shapley 1967).

If we wish to ensure that players are tightly retained, it is natural to consider stronger requirements. Let us consider the following two extensions of the core.

- For \( \epsilon \in \mathbb{R} \), we say that a value division \( x \in \mathbb{R}^V \) is in the strong \((\epsilon)-\)core if the loss of a deviating nontrivial coalition is at least \( \epsilon \), that is, \( x(S) - \nu(S) \geq \epsilon \) for any \( \emptyset \nsubseteq S \nsubseteq V \).

- For \( \epsilon \in \mathbb{R} \), we say that a value division \( x \in \mathbb{R}^V \) is in the weak \((\epsilon)-\)core if the loss of a deviating nontrivial coalition is at least \( \epsilon \) on average, that is, \( x(S) - \nu(S) \geq \epsilon|S| \) for any \( \emptyset \nsubseteq S \nsubseteq V \).

Note that the core is equal to the strong \( 0\)-core and the weak \( 0\)-core.

The strong least core value of a game is the minimum \( \epsilon \in \mathbb{R} \) such that the strong \( \epsilon\)-core is nonempty. The strong least core of a game is the strong \( \epsilon\)-core for the strong least core value \( \epsilon \). The weak least core value and the weak least core are defined analogously using the notion of the weak \( \epsilon\)-core. Note that the strong and the weak least core values of a supermodular game are always nonpositive because the core is nonempty. Hence, it is convenient to consider the strong and weak \((\epsilon)-\)cores instead of the strong and the weak \( \epsilon\)-cores.

Let \( \delta^s(\epsilon, S) = \epsilon \) and \( \delta^w(\epsilon, S) = \epsilon|S| \). The strong and weak least core values of a cooperative game can be computed by solving the following linear program (LP).

\[
\begin{align*}
\text{min} & \quad -\epsilon \\
\text{s.t} & \quad x(S) \geq \nu(S) + \delta^y\nu^p(\epsilon, S) \quad \forall \emptyset \nsubseteq S \nsubseteq V \\
& \quad x(V) = \nu(V) \\
& \quad x(v) \geq 0 \quad \forall v \in V, \quad (1)
\end{align*}
\]
where type is ‘s’ in the strong core case and ‘w’ in the weak core case. Note that, for supermodular games, \( \epsilon \geq 0 \) holds in the optimal solution.

**Characterizations of Least Cores**

In this section, we characterize the strong and weak least core values of a supermodular game.

Let \((V, \nu)\) be a supermodular game. Instead of solving the optimization problem (1), we fix \(\epsilon \geq 0\) and consider its feasibility. We define a function \(f^{\text{type}} : 2^V \rightarrow \mathbb{R}\) as

\[
f^{\text{type}}(S) = \begin{cases} 0 & \text{if } S = \emptyset, \\ -\nu(S) - \delta^{\text{type}}(\epsilon, S) & \text{if } 0 \leq S \subsetneq V, \\ -\nu(V) & \text{if } S = V. \end{cases}
\]

It is clear that \(f^{\text{type}}\) is crossing submodular (but not necessarily submodular).

The feasibility version of (1) can then be rephrased as follows:

\[
x(S) \leq f^{\text{type}}(S), \quad \forall \emptyset \subseteq S \subsetneq V,\\
x(V) = f^{\text{type}}(V),\\
x(v) \leq 0, \quad \forall v \in V.
\]

(2)

Note that the variable \(x(v)\) is negated for each \(v \in V\).

For a function \(f : 2^V \rightarrow \mathbb{R}\), we can write the (generalized) extended polymatroid associated with \(f\) as

\[
P_f = \{x \in \mathbb{R}^V \mid x(S) \leq f(S) \text{ for all } \emptyset \subseteq S \subsetneq V\}.
\]

We define \(p^{\text{type}} = \max\{x(V) \mid x \in P(f^{\text{type}})\}\). Then, the program (2) is feasible if and only if \(p^{\text{type}} \geq f^{\text{type}}(V)\).

It is known that \(p^{\text{type}}\) can be computed in polynomial time (Frank and Tardos 1988; Naitoh and Fujishige 1992). However, as the algorithm is cumbersome to describe and implement, we further simplify the problem using the properties of supermodular cooperative games. We use the following theorem.

**Theorem 1** (Fujishige 1984). Let \(f : 2^V \rightarrow \mathbb{R}\) be a crossing submodular function and let \(p = \max\{x(V) \mid x \in P(f)\}\). Let \(q, r \in \mathbb{R}\) be defined as

\[
q = \min_{S \in P_2(V)} \sum_{S \subseteq S} f(S),\\
r = \min_{S \in P_2(V)} \frac{1}{|S|-1} \sum_{S \subseteq S} f(S).
\]

Then, we have \(p = \min\{q, r\}\).

Consider Theorem 1 instantiated with the function \(f^{\text{type}}\), and set \(q = q^{\text{type}}\) and \(r = r^{\text{type}}\). From Theorem 1, the program (2) is feasible if and only if

\[
\min\{q^{\text{type}}, r^{\text{type}}\} \geq f^{\text{type}}(V).
\]

We now derive the strong and weak least core values using (3).

**Theorem 2.** The strong least core value of a supermodular game \((V, \nu)\) is

\[
-\min_{S \in P_2(V)} \frac{1}{|S|} \left( \nu(V) - \sum_{S \subseteq S} \nu(S) \right),
\]

\[
\min_{S \in P_2(V)} \frac{1}{|S|} \left( (|S|-1)\nu(V) - \sum_{S \subseteq S} \nu(S) \right).
\]

\[
= \nu(V) - \frac{1}{|S|-1} \sum_{S \subseteq S} (\nu(S) + \delta^\nu(\epsilon, S))
\]

\[
= \nu(V) - \frac{1}{|S|-1} \sum_{S \subseteq S} \nu(S) - \epsilon|V|.
\]

\[
= \nu(V) - \frac{1}{|S|-1} \sum_{S \subseteq S} \nu(S) - \epsilon|V|.
\]

\[
\text{Proof.} \text{ Note that the strong least core value is } -\epsilon \text{ for the maximum } \epsilon \geq 0 \text{ such that (3) holds, where the type is ‘s’}. \]

We first consider the condition \(q^\epsilon \geq f^\epsilon(V)\). Let \(S \in \mathcal{P}_2(V)\) be a partition of \(V\). We then have

\[
\sum_{S \subseteq S} f^\epsilon(S) - f^\epsilon(V) \geq \nu(V) - \sum_{S \subseteq S} (\nu(S) + \delta^\nu(\epsilon, S))
\]

\[
= \nu(V) - \sum_{S \subseteq S} \nu(S) - \epsilon|S|.
\]

Hence, \(q^\epsilon \geq f^\epsilon(V)\) holds if and only if \(\nu(V) - \sum_{S \subseteq S} \nu(S) - \epsilon|S| \geq 0\) holds for any partition \(S \in \mathcal{P}_2(V)\).

Next, we consider the condition \(r^\epsilon \geq f^\epsilon(V)\). Let \(S \in \mathcal{P}_2(V)\) be a copartition of \(V\). We then have

\[
\frac{1}{|S|-1} \sum_{S \subseteq S} f^\epsilon(S) - f^\epsilon(V)
\]

\[
= \nu(V) - \frac{1}{|S|-1} \sum_{S \subseteq S} (\nu(S) + \delta^\nu(\epsilon, S))
\]

\[
= \nu(V) - \frac{1}{|S|-1} \sum_{S \subseteq S} \nu(S) - \epsilon|S|.
\]

Hence, \(r^\epsilon \geq f^\epsilon(V)\) holds if and only if \(\nu(V) - \frac{1}{|S|-1} \sum_{S \subseteq S} \nu(S) - \epsilon|S| \geq 0\) holds for any partition \(S \in \mathcal{P}_3(V)\).

Combining the two cases, we obtain the desired value. Note that a partition into two parts can be regarded as a copartition into two parts. Hence, we can replace \(\mathcal{P}_3\) by \(\mathcal{P}_2\).

\[
\text{Theorem 3.} \text{ The weak least core value of a supermodular game } (V, \nu) \text{ is}
\]

\[
-\frac{1}{|V|} \min_{S \in \mathcal{P}_2(V)} \left( \nu(V) - \frac{1}{|S|-1} \sum_{S \subseteq S} \nu(S) \right).
\]

\[
\text{Proof.} \text{ Note that the weak least core value is } -\epsilon \text{ for the maximum } \epsilon \geq 0 \text{ such that (3) holds, where the type is ‘w’}. \]

We first consider the condition \(q^w \geq f^w(V)\). Let \(S \in \mathcal{P}_2(V)\) be a partition of \(V\). We then have

\[
\sum_{S \subseteq S} f^w(S) - f^w(V) \geq \nu(V) - \sum_{S \subseteq S} (\nu(S) + \delta^w(\epsilon, S))
\]

\[
= \nu(V) - \sum_{S \subseteq S} \nu(S) - \epsilon|V|.
\]

Since \(\nu\) is supermodular, (5) is minimized when \(S\) is a partition into two parts. Hence, \(q^w \geq f^w(V)\) holds if and only if \(\nu(V) - (\nu(S_1) + \nu(S_2)) - \epsilon|V| \geq 0\) holds for any partition \(\{S_1, S_2\}\) of \(V\).

Next, we consider the condition \(r^w \geq f^w(V)\). Let \(S \in \mathcal{P}_2(V)\) be a copartition of \(V\). We then have

\[
\frac{1}{|S|-1} \sum_{S \subseteq S} f^w(S) - f^w(V)
\]

\[
= \nu(V) - \frac{1}{|S|-1} \sum_{S \subseteq S} (\nu(S) + \delta^w(\epsilon, S))
\]

\[
= \nu(V) - \frac{1}{|S|-1} \sum_{S \subseteq S} \nu(S) - \epsilon|V|.
\]
Hence, \( r^G \geq f^w(V) \) holds if and only if \( \nu(V) - \frac{1}{|S|} \sum_{S \in \mathcal{S}} \nu(S) - c(V) \geq 0 \) holds for any copartition \( S \in \mathcal{P}_2(V) \).

To summarize, (3) holds if and only if \( \nu(V) - \frac{1}{|S|} \sum_{S \in \mathcal{S}} \nu(S) - c(V) \geq 0 \) holds for any copartition \( S \in \mathcal{P}_2(V) \), which means that the weak least core value is

\[
\min_{S \in \mathcal{P}_2(V)} \frac{1}{|V|} \left( \nu(V) - \frac{1}{|S|} \sum_{S \in \mathcal{S}} \nu(S) \right).
\]

### Induced Subgraph Game

Let \( G = (V, E, w) \) be a weighted hypergraph, where \( V \) is a set of vertices, \( E \) is a set of hyperedges, and \( w : E \rightarrow \mathbb{R}_+ \) is a weight function on the hyperedges. We often regard a hyperedge \( e \in E \) as a subset of \( V \). The induced subgraph game associated with \( G \) is the cooperative game \( (V, \nu) \), where \( \nu : 2^V \rightarrow \mathbb{R}_+ \) is the total weight of the hyperedges \( e \in E \) with \( e \subseteq V \). Note that \( \nu \) is supermodular.

In this section, we consider induced subgraph games. We derive explicit forms of the strong and weak least core values, and present polynomial-time algorithms that compute the value divisions in the strong and weak least cores.

### Definitions

Let \( S \subseteq V \) be a set of vertices. We say that a hyperedge \( e \in E \) is cut by \( S \) if \( e \not\subseteq S \) and \( e \not\subseteq V \setminus S \). The cut weight of \( S \), denoted by \( c(S) \), is the total weight of the hyperedges cut by \( S \). A vertex set with the minimum cut weight is called a minimum cut. Let \( c^*(G) \) denote the weight of the minimum cut of \( G \).

Let \( S \) be a partition of \( V \) into at least two nontrivial parts. We say that a hyperedge \( e \in E \) is cut by \( S \) if \( e \not\subseteq S \) for any \( S \in \mathcal{S} \). The cut weight of a partition \( S \) of \( V \), denoted by \( c(S) \), is the total weight of hyperedges cut by \( S \). We define \( c(S) \) as \( \sum_{S \in \mathcal{S}} c(S) - c(S) \). That is, we count a hyperedge \( e \in E \) exactly \( \ell \) times if it intersects with \( \ell + 1 \) parts of \( S \).

### Characterization of the strong least core value

We first derive the strong least core value of induced subgraph games.

**Theorem 4.** The strong least core value of the induced subgraph game associated with a hypergraph \( G = (V, E, w) \) is

\[
- \frac{c^*(G)}{2}.
\]

**Proof.** From Theorem 2, the strong least core value is

\[
- \min \left\{ \frac{1}{|S|} \left( \nu(V) - \sum_{S \in \mathcal{S}} \nu(S) \right) \right\},
\]

\[
\min \left\{ \frac{1}{|S|} \left( (|S| - 1) \nu(V) - \sum_{S \in \mathcal{S}} \nu(S) \right) \right\}.
\]

For a partition \( S \in \mathcal{P}_2(V) \), we have

\[
\nu(V) - \sum_{S \in \mathcal{S}} \nu(S) = c(S).
\]

For a copartition \( S \in \mathcal{P}_2(V) \), we have

\[
(|S| - 1) \nu(V) - \sum_{S \in \mathcal{S}} \nu(S) = \left( \frac{|S| - 1}{|S|} \right) \nu(V) - \sum_{S \in \mathcal{S}} \nu(S).
\]

### Characterization of the weak least core value

We now derive the weak least core value of induced subgraph games.

**Theorem 6.** The weak least core value of the induced subgraph game associated with a hypergraph \( G = (V, E, w) \) is

\[
- \frac{1}{|V|} \min_{S \in \mathcal{P}_2(V)} \left[ \frac{c(S)}{|S| - 1} \right].
\]

**Proof.** From Theorem 3, the weak least core value is

\[
\frac{1}{|V|} \min_{S \in \mathcal{P}_2(V)} \left[ \nu(V) - \frac{1}{|S| - 1} \sum_{S \in \mathcal{S}} \nu(S) \right].
\]

Using the calculation in the proof of Theorem 4 (for the copartition case), we have the desired result.
Suppose that the input hypergraph is a graph. Then, the value of \( c(S) \) is equal to \( \frac{c(S)}{2} \). The value \( \min_{S \subseteq \mathcal{F}(V)} \frac{c(S)}{2} \) is called the strength, which is another notion representing how the graph is well clustered, and it can be computed in polynomial time (Cunningham 1985).

**Algorithm for the strong least core**

In this subsection, we provide a polynomial-time algorithm that computes a value division in the strong least core of the induced subgraph game associated with a hypergraph \( G = (V, E, w) \). To this end, we construct a separation oracle for the LP (1), which returns a constraint (if any) that is not satisfied in the current LP solution \((\varepsilon, x)\). Using the ellipsoid method (Khachiyan 1980), we can then solve LP (1) by calling the separation oracle polynomially many times in \( n \).

The separation oracle is constructed as follows. As the last two constraints of the LP (1) are easy to check, we assume that the current solution \((\varepsilon, x)\) satisfies these constraints.

We now wish to check \( x(S) \geq \nu(S) + \varepsilon \) for any \( \emptyset \subseteq S \subseteq V \). This problem can be reduced to the minimum cut problem. We first construct a hypergraph \( G' = (V', E', w') \) from \( G \) as follows: define \( V' = V \cup \{s, t\} \), where \( s \) and \( t \) are new vertices. For each hyperedge \( e \in E \), add a hyperedge \( e \cup \{s\} \) of the same weight to \( E' \). Finally, for each \( v \in V \), add a hyperedge \( \{v, t\} \) of weight \( x(v) \). An example of this reduction is shown in Figure 1. For a set of vertices \( S \subseteq V \), the cut weight of \( S \cup \{s\} \) in \( G' \) is

\[
\nu(V) + x(S) - \nu(S).
\]

Hence, it suffices to check that the cut weight of \( S \cup \{s\} \) is at least \( \nu(V) + \varepsilon \) for all \( \emptyset \subseteq S \subseteq V \).

This problem is almost equivalent to finding a minimum \( s-t \) cut in \( G' \), except that we need to exclude trivial cuts \( \{s\} \) and \( V \cup \{s\} \). To this end, for each pair of vertices \( (u, v) \), we construct a hypergraph \( G_{uv}' \) by contracting \( u \) to \( s \) and \( v \) to \( t \). Note that for any \( S \subseteq V \setminus \{u, v\} \), the cut weight of \( S \cup \{s\} \) in \( G_{uv}' \) is equal to the cut weight of \( S \cup \{u, s\} \) in \( G' \). Hence, by taking the minimum cut weight of \( G_{uv}' \) over all possible pairs \( (u, v) \) and checking that it is at least \( \nu(V) + \varepsilon \), we can find the constraint violated by the current LP solution \((\varepsilon, x)\).

The algorithm proposed by (Pistorius and Minoux 2003) can be used to compute the minimum cut of a hypergraph.

**Algorithm 1**

**Input:** A hypergraph \( G = (V, E, w) \).

**Output:** The strong least core value of \( G \).

1: Solve LP (1) using the ellipsoid method with SEPARATION-ORACLE, and return \(-\varepsilon\).
2: **procedure** SEPARATION-ORACLE(\( \varepsilon, x) \)
3: if \( x(V) \neq \nu(V) \) or \( x(v) < 0 \) for some \( v \in V \) then
4: return the violated constraint.
5: Construct a hypergraph \( G' \) from \( G \).
6: for each \( u, v \in V \) do
7: \( S \leftarrow \) the minimum cut of \( G'_{uv} \).
8: if \( c(S) < \nu(V) + \varepsilon \) then
9: return the violated constraint.
10: **return** by saying no constraint is violated.

The overall algorithm is given in Algorithm 1. In summary, we have the following:

**Theorem 7.** We can compute a value division in the strong and weak least cores of a hypergraph \( G = (V, E, w) \) in \( O(|V|^2 f(|V|, O(\sum_{e \in E} |e|))L) \) time, where \( f(n, m) \) is the time complexity of solving the max flow problem on a graph consisting of \( n \) vertices and \( m \) edges, and \( L \) is the number of times that the separation oracle is called by the ellipsoid method, which is polynomial in \(|V|\) and \(|E|\).

**Algorithm for the weak least core**

In this subsection, we briefly discuss a polynomial-time algorithm that computes a value division in the weak least core of the induced subgraph game associated with a hypergraph \( G = (V, E, w) \).

The algorithm is almost identical to that for the strong least core. The only difference is the implementation of the separation oracle, which can be summarized as follows: (i) Check that the current solution satisfies \( x(v) \geq \varepsilon \) for all \( v \in V \) instead of checking \( x(v) \geq 0 \). (ii) When constructing an auxiliary graph the weight of the hyperedge \( \{v, t\} \) is \( x(v) - \varepsilon \) instead of \( x(v) \). See Figure 1 for an example of the reduction. (iii) The cut weight of \( S \cup \{s\} \) is then \( \nu(V) + x(S) - \varepsilon |S| - \nu(S) \).

Hence, it suffices to check that the cut weight of \( S \cup \{s\} \) is at least \( \nu(V) \) for all \( \emptyset \subseteq S \subseteq V \).
**Airport Game**

In this section, we consider the airport game. An instance of the airport game is a tuple $I = (n, c_1, \ldots, c_n)$, where $n$ is an integer and $c_1, \ldots, c_n \in \mathbb{R}_+$ with $c_1 \leq c_2 \leq \cdots \leq c_n$. Let $V = [n]$. We define 

$$\nu(S) = -\max_{i \in S} c_i$$

for each set $S \subseteq V$. Then, the cooperative game associated with $I$ is $(V, \nu)$. In the example of sharing taxis, $c_i$ denotes the fare of the $i$-th customer, and the fare for a group $S \subseteq V$ is $\max_{i \in S} c_i$, that is, the fare for the customer whose destination is farthest away.

**Characterization of the strong least core**

We derive a closed formula for the strong least core value of the airport game.

**Theorem 8.** The strong least core value of the airport game associated with an instance $I = (n, c_1, \ldots, c_n)$ is

$$-\frac{1}{n} \min_{k \in [n-1]} \frac{c_k}{k + 1}.$$

**Proof.** From Theorem 2, the strong least core value is

$$-\min \left\{ \frac{1}{S \in \mathcal{P}_2} \left( \nu(V) - \sum_{S \in S} \nu(S) \right), \frac{1}{S \in \mathcal{P}_2} \left( (|S| - 1) \nu(V) - \sum_{S \in S} \nu(S) \right) \right\}.$$ 

The first term is 

$$\min_{S \in \mathcal{P}_2} \frac{1}{|S|} \left( \sum_{S \in S} \max_{i \in S} c_i - c_n \right) = \min_{2 \leq k \leq n} \frac{1}{k} \sum_{i \in [k-1]} c_i.$$ 

The second term is 

$$\min_{S \in \mathcal{P}_2} \frac{1}{|S|} \left( \sum_{S \in S} \max_{i \in S} - (|S| - 1) c_n \right)$$

$$= \min_{2 \leq k \leq n} \frac{1}{k} \left( (k-1) c_n + c_{k-1} - (k-1) c_n \right) = \frac{c_{k-1}}{k}.$$

Since $c_{k-1} \leq \sum_{i \in [k-1]} c_i$, we have the desired result. $\square$

**Theorem 9.** The strong least core value $-\epsilon$, where $\epsilon := \frac{1}{n} \min_{k \in [n-1]} \frac{c_k}{k + 1}$, of the airport game associated with an instance $I = (n, c_1, \ldots, c_n)$ is achieved by the following value division $x \in \mathbb{R}^V$:

$$x(i) = -\epsilon \ (i \in [n-1]) \text{ and } x(n) = -c_n + \epsilon (n-1).$$

**Proof.** First, we have $x([n]) = -c_n = \nu([n])$. In the following, we check that $x(S) \geq \nu(S) + \epsilon$ holds for any $\emptyset \subsetneq S \subsetneq V$.

Note that $x(i) = -\epsilon \leq 0$ for all $i \in [n-1]$ and $x(n) = -c_n + \epsilon (n-1) \leq c_{n-2} - c_n \leq 0$. Hence, we need only consider sets of the form $[k]$ for each $k \in [n-1]$ and $[n] \setminus [k]$ for each $k \in [n-1]$. Specifically, we check the following conditions: (i) $x([k]) \geq \nu([k]) + \epsilon$ for each $k \in [n-1]$, and (ii) $x([n]) - x(k) \geq \nu([n]) + \epsilon$ for each $k \in [n-1]$. Since $x([k]) = -c_k + \nu([k]) = -c_k$, the former condition is equivalent to $\epsilon (k+1) \leq c_k$ for each $k \in [n-1]$, which is true. Since $x([n]) = \nu([n])$ and $x(k) = -\epsilon$, the latter condition is trivially true. $\square$

**Characterization of the weak least core**

We derive a closed formula for the weak least core value of the airport game.

**Theorem 10.** The weak least core value of the airport game associated with an instance $I = (n, c_1, \ldots, c_n)$ is

$$-\frac{1}{n} \min_{S \in \mathcal{P}_2} \frac{1}{|S|-1} \left( (|S| - 1) \nu(V) - \sum_{S \in S} \nu(S) \right),$$

which is

$$-\frac{1}{n} \min_{S \in \mathcal{P}_2} \frac{1}{|S|-1} \left( \sum_{S \in S} \max_{i \in S} c_i - (|S| - 1) c_n \right)$$

$$= -\frac{1}{n} \min_{2 \leq k \leq n} \frac{1}{k - 1} \left( (k-1) c_n + c_{k-1} - (k-1) c_n \right)$$

$$= -\frac{1}{n} \min_{2 \leq k \leq n} \frac{c_{k-1}}{k - 1} = -\frac{1}{n} \min_{k \in [n-1]} \frac{c_k}{k}.$$ $\square$

**Theorem 11.** The weak least core value $-\epsilon$, where $\epsilon := \frac{1}{n} \min_{k \in [n-1]} \frac{c_k}{k}$ of an instance $I = (n, c_1, \ldots, c_n)$ of the airport game is achieved by the following value division $x \in \mathbb{R}^V$:

$$x(i) = -\epsilon (n-1) \ \forall i \in [n-1],$$

$$x(n) = -c_n + \epsilon (n-1)^2.$$ 

**Proof.** Note that $x([n]) = -c_n = \nu([n])$. In the following, we check that $x(S) \geq \nu(S) + \epsilon |S|$ holds for any $\emptyset \subsetneq S \subsetneq V$.

Let $\emptyset \subsetneq S \subsetneq V$ be a set. If $n \notin S$, then we have that $x(S) - \nu(S) = c_j - \epsilon (n-1) |S| \geq c_j - \epsilon |S|$ for $j = \max \{ i \in S \}$ if $n \in S$, then we have $x(S) - \nu(S) = \epsilon (n-1) (|n-1| - |S|) = \epsilon (n-1) (n-|S|) \geq \epsilon |S|$. $\square$

**Conclusion**

The contributions reported in this paper can be summarized as follows: First, we provided theoretical characterizations of the strong and weak least core values of a supermodular game. We then derived explicit and concise formulas for the strong and weak least core values of the induced subgraph game and the airport game, and presented polynomial-time algorithms for computing the value divisions in the strong and weak least cores. It should be noted that, although space limitations mean that we have only provided formulas for two supermodular games, we could easily analyze other supermodular games using a similar reasoning.
