Abstract
We establish a link between multiwinner elections and apportionment problems by showing how approval-based multiwinner election rules can be interpreted as methods of apportionment. We consider several multi-winner rules and observe that some, but not all, of them induce apportionment methods that are well established in the literature and in the actual practice of proportional representation. For instance, we show that Proportional Approval Voting induces the D’Hondt method and that Monroe’s rule induces the largest remainder method. We also consider properties of apportionment methods and exhibit multiwinner rules that induce apportionment methods satisfying these properties.

1 Introduction
The study of preference aggregation mechanisms—in particular, voting rules—is an important part of multiagent systems research (e.g., Conitzer 2010). Recent years have witnessed an increasing interest in multiwinner elections. In this setting, there is a set of agents who entertain preferences over a set of alternatives. Based on these preferences, the goal is to select a committee, i.e., a (fixed-size) subset of the alternatives. Preferences are usually specified either as rankings, i.e., complete linear orders over the set of all alternatives (e.g., Elkind et al. 2014), or as approval votes, i.e., yes/no assessments of all the alternatives (e.g., Kilgour 2010). We are particularly interested in the latter variant, in which each agent can be thought of as specifying a subset of alternatives that are “acceptable” for that agent.

The decision scenario modeled by multiwinner elections—selecting a subset of objects from a potentially much larger pool of available objects—is ubiquitous: consider, e.g., picking players to form a sports team, selecting items to display in an online shop, choosing the board of directors of a company, etc. Many of these scenarios are reminiscent of parliamentary elections, a topic that has been studied in great detail by political scientists. In a parliamentary election, the candidates are traditionally organized in political parties and the election determines how many parliamentary seats a party is allocated.

Under so-called proportional representation systems with “closed party lists,” a voter is allowed to give her vote to one and only one party.1 In a sense, this forces the voter to approve all candidates from one party and no candidates from any other party. Counting such ballots, and deciding how many candidates are elected from each list, is an apportionment problem. Any apportionment problem can thus be seen as a very simple approval voting instance: all voters approve all the candidates from their chosen party, and only those.

The present paper formally establishes and explores this analogy between multiwinner elections and apportionment problems. We show how an apportionment problem can be phrased as an instance of an approval-based multiwinner election, thereby rendering multiwinner rules applicable to the apportionment setting. As a result, every approval-based multiwinner rule induces a method of apportionment. Exploring this link between multiwinner rules and apportionment methods is interesting for at least two reasons. First, observing what kind of apportionment method a given multiwinner rule induces yields new insights into the nature of the rule. Second, every multiwinner rule inducing a given apportionment method can be seen as an extension of the apportionment method to a more general setting where candidates have no party affiliations (or party affiliations are ignored in the election process).

After formally establishing the link between approval-based multiwinner rules and apportionment methods, we consider several multiwinner rules and observe that they induce (and extend) apportionment methods that are well-established in the apportionment literature. For instance, Proportional Approval Voting induces the D’Hondt method (aka Jefferson method) and Monroe’s rule induces the largest remainder method (aka Hamilton method). We also consider properties of apportionment methods (such as lower quota or the Penrose condition) and exhibit multiwinner rules that induce apportionment methods satisfying these properties.

The paper is organized as follows. Section 2 introduces both the apportionment problem and the multiwinner election setting. Section 3 shows how approval-based multiwinner...
ner rules can be employed as apportionment methods, and contains several results related to proportional representation. Section 4 is devoted to non-proportional representation in the form of degressive proportionality and thresholds, and Section 5 concludes. All proofs can be found in the full version of this paper (Brill, Laslier, and Skowron 2016).

## 2 The Apportionment Problem and Approval-Based Multiwinner Elections

In this section we provide the formal setting of the apportionment problem and of approval-based multiwinner elections, and we define several apportionment methods and multiwinner rules. (Examples illustrating these methods can be found in the full version of this paper.) For a natural number \( t \in \mathbb{N} = \{1, 2, \ldots, t\} \), let \([t]\) denote the set \(\{1, 2, \ldots, t\}\).

### 2.1 Apportionment Methods

In the apportionment setting, there is a finite set of voters and a finite set of \( p \) parties \( P_1, \ldots, P_p \). Every voter votes for exactly one party, and for each \( i \in [p] \), we let \( v_i \) denote the number of votes that party \( P_i \) receives, i.e., the number of voters who voted for \( P_i \). The goal is to allocate \( h \) (parliamentary) seats among the parties. Formally, an instance of the apportionment problem is given by a tuple \((v,h)\), where \( v = (v_1, \ldots, v_p) \in \mathbb{N}^p \) is the vote distribution and \( h \) is the number of seats to distribute. We use \( v_+ \) to denote the total number of votes, \( v_+ = \sum_{i=1}^{p} v_i \). Throughout this paper, we assume that \( v_i > 0 \) for all \( i \in [p] \) and \( h > 0 \).

An apportionment method \( M \) maps every instance \((v,h)\) to a nonempty set \( M(v,h) \) of seat distributions. A seat distribution is a vector \( (x_1, \ldots, x_p) \in \mathbb{N}^p \) with \( \sum_{i=1}^{p} x_i = h \). Here, \( x_i \) corresponds to the number of seats allocated to party \( P_i \).

#### Divisor Methods

A rich and very well-studied class of apportionment methods is defined via divisor sequences.

**Definition 1.** Let \( d = (d(0), d(1), d(2), \ldots) \) be a sequence with \( 0 < d(j) \leq d(j + 1) \) for all \( j \in \mathbb{N}_0 \). The divisor method based on \( d \) is the apportionment method that maps a given instance \((v,h)\) to the set of all seat allocations that can result from the following procedure: Start with the empty seat allocation \((0, \ldots, 0)\) and iteratively assign a seat to a party \( P_i \) maximizing \( \frac{v_i}{d(s_i)} \) where \( s_i \) is the number of seats that have already been allocated to party \( P_i \).

Divisor methods are often defined in a procedurally different, but mathematically equivalent way (see Balinski and Young 1982, Proposition 3.3).\(^3\) Two prominent divisor methods are due to D’Hondt and Sainte-Lagué.

**Definition 2 (D’Hondt method).** The D’Hondt method (aka Jefferson method or Hagenbach-Bischoff method) is the divisor method based on \( d = (1, 2, 3, \ldots) \). Therefore, in each round, a seat is allocated to a party \( P_i \) maximizing \( \frac{v_i}{s_i(d)(s_i)} \), where \( s_i \) is the number of seats that have already been allocated to party \( P_i \).

**Definition 3 (Sainte-Lagué method).** The Sainte-Lagué method (aka Webster method, Schepers method, or method of major fractions) is the divisor method based on \( d = (1, 3, 5, \ldots) \). Therefore, in each round, a seat is allocated to a party \( P_i \) maximizing \( \frac{v_i}{s_i(d)1} \), where \( s_i \) is the number of seats that have already been allocated to party \( P_i \).

### 2.2 Approval-Based Multiwinner Election Rules

We now introduce the setting of approval-based multiwinner elections. We have a finite set \( N = \{1, 2, \ldots, n\} \) of voters and a finite set \( C = \{c_1, c_2, \ldots, c_m\} \) of candidates. Each voter expresses their preferences by approving a subset of candidates, and we want to select a committee consisting of exactly \( k \) candidates. We will refer to \( k \)-element subsets of \( C \) as size-\( k \) committees, and we let \( A_i \subseteq C \) denote the set of candidates approved by voter \( i \in N \). Formally, an instance of the approval-based multiwinner election problem is given by a tuple \((A,k)\), where \( A = (A_1, A_2, \ldots, A_n) \) is a preference profile and \( k \) is the desired committee size. An approval-based multiwinner election rule (henceforth multiwinner rule) \( \mathcal{R} \) is a function that maps every instance \((A,k)\) to a nonempty set \( \mathcal{R}(A,k) \) of size-\( k \) committees. Every

---

\(^2\)In order to accommodate for symmetric instances, apportionment methods are allowed to output several seat distributions.

\(^3\)In order to accommodate for symmetric instances, multiwinner rules are allowed to output multiple committees.
element of \( R(A, k) \) is referred to as a winning committee.

**OWA-Based Rules** A remarkably general class of multiwinner election rules is defined via ordered weighted averaging (OWA) operators (Thiele 1895; Yager 1988; Skowron, Faliszewski, and Lang 2015). A weight sequence is an infinite sequence of real numbers \( w = (w_1, w_2, \ldots) \).

**Definition 6** (OWA-based rules). Consider a weight sequence \( w = (w_1, w_2, \ldots) \), a subset \( S \subseteq C \) of candidates, and a voter \( i \). The satisfaction of \( i \) from \( S \) given \( w \) is defined as \( u_i^w(S) = \sum_{j=1}^{\lvert A_i \cap S \rvert} w_j \). Given an instance \((A, k)\) of the multiwinner election problem, the \( w \)-based OWA rule selects all size-\( k \) committees \( S \) maximizing the total satisfaction \( \sum_{i \in N} u_i^w(S) \).

Note that multiplying a weight sequence \( w \) by a positive constant does not change the way in which a rule operates. Several established multiwinner election rules can be described as OWA-based rules.

**Definition 7.** The Chamberlin–Courant rule is the OWA-based rule with weight sequence \( w_{CC} = (1, 0, 0, \ldots) \).

The Chamberlin–Courant rule is usually defined in the context of elections where voter preferences are given by ranked ballots (Chamberlin and Courant 1983); our definition is a straightforward adaption to the approval setting.

**Definition 8.** Proportional Approval Voting (PAV) is the OWA-based rule with weight sequence \( w_{PAV} = (1, \frac{1}{2}, \frac{1}{2}, \ldots) \).

Though sometimes attributed to Forest Simmons, PAV was already proposed and discussed by the Danish polymath Thorvald N. Thiele in the 19th century (Thiele 1895; Janson 2016). According to PAV, each voter cares about the whole committee, but the marginal gain of satisfaction of an already satisfied voter from an additional approved committee member is lower than the gain of a less satisfied voter. The reason for using the particular weight sequence \( w_{PAV} \) is not obvious. Aziz et al. (2017) and Sánchez-Fernández et al. (2017) provide compelling arguments by showing that \( w_{PAV} \) is the unique weight sequence \( w \) such that the \( w \)-based OWA rule satisfies certain axiomatic properties. Theorem 2 in the present paper can be viewed as an additional—though related—argument in favor of the weight sequence \( w_{PAV} \).

**Definition 9.** The top-\( k \) rule is the OWA-based rule with weight sequence \( w_{top-k} = (1, 1, 1, \ldots) \).

According to the top-\( k \) rule, the winning committee contains the \( k \) candidates that have been approved by the greatest number of voters.

**Sequential OWA-Based Rules** Another interesting class of multiwinner election systems consists of sequential variants of OWA-based rules.

**Definition 10.** The sequential \( w \)-based OWA rule selects all committees that can result from the following procedure. Starting with the empty committee \((S = \emptyset)\), in \( k \) consecutive steps add to the committee \( S \) a candidate \( c \) that maximizes \( \sum_{i \in N} u_i^w(S \cup \{c\}) - u_i^w(S) \).

Just like OWA-based rules, sequential OWA-based rules have already been considered by Thiele (1895).

**Monroe’s Rule** The optimization problem underlying the Chamberlin–Courant rule can be thought of in terms of maximizing representation: every voter is assigned to a single candidate in the committee and this “representative” completely determines the satisfaction that the voter derives from the committee. The rule proposed by Monroe (1995) is based on the same idea; however, Monroe requires each candidate to represent the same number of voters. For the sake of simplicity, when considering the Monroe rule we assume that the number of voters \( n \) is divisible by the size of the committee \( k \).

**Definition 11.** Consider an instance \((A, k)\) such that \( k \) divides \( n \) and let \( S \) be a size-\( k \) committee. A balanced allocation of the voters to the candidates in \( S \) is a function \( \tau_S : N \rightarrow S \) such that \( \lvert \tau_S^{-1}(c) \rvert = \frac{n}{k} \) for all \( c \in S \). The satisfaction \( u_i(\tau_S) \) of a voter \( i \) from \( \tau_S \) is equal to one if \( i \) approves of \( \tau_S(i) \), and zero otherwise. The total satisfaction of voters provided by \( S \), denoted \( u(S) \), is defined as the satisfaction from the best balanced allocation, i.e., \( u(S) = \max_{\tau_S} \sum_{i \in N} u_i(\tau_S) \). The Monroe rule selects all size-\( k \) committees \( S \) maximizing \( u(S) \).

**4’s Rules** In the late 19th century, Swedish mathematician Lars Edvard Phragmén proposed a load-balancing approach for selecting committees (Phragmén 1894; Janson 2016). Here, we formulate two particularly interesting variants (see Brill et al. 2017).

The motivation behind Phragmén’s rules is to find a committee whose “support” is distributed as evenly as possible among the electorate. For every candidate in the committee, one unit of “load” needs to be distributed among the voters approving this candidate. The goal is to find a committee of size \( k \) for which the maximal load of a voter (or the variance of the load distribution) is as small as possible.

**Definition 12.** Consider an instance \((A, k)\) of the multiwinner election problem. A load distribution for \((A, k)\) is a matrix \( L = (l_{i,c})_{i \in N, c \in C} \in \mathbb{R}^{N \times |C|} \) such that (i) \( \sum_{i \in N} \sum_{c \in C} l_{i,c} = k \), (ii) \( \sum_{i \in N} l_{i,c} \in \{0, 1\} \) for all \( c \in C \), and (iii) \( l_{i,c} = 0 \) if \( c \notin A \). Every load distribution \( L \) corresponds to a size-\( k \) committee \( c \in C : \sum_{i \in N} l_{i,c} = 1 \).

The multiwinner election rules max-Phragmén and var-Phragmén are defined as optimization problems over the set of all load distributions.

**Definition 13.** The rule max-Phragmén selects all size-\( k \) committees corresponding to load distributions \( L \) minimizing \( \max_{i \in N} \sum_{c \in C} l_{i,c} \). The rule var-Phragmén selects all size-\( k \) committees corresponding to load distributions \( L \) minimizing \( \sum_{i \in N} \sum_{c \in C} l_{i,c}^2 \).

**3 Apportionment Via Multiwinner Rules** In this section we demonstrate how approval-based multiwinner rules can be employed as apportionment methods. For a given instance \((v, h)\) of the apportionment problem and a multiwinner rule \( R \), this procedure involves three steps:

1. Translate \((v, h)\) into an instance \((A, k)\) of the multiwinner election problem.

416
2. Apply the multiwinner rule \( \mathcal{R} \) to \((A, k)\).
3. Translate committee(s) in \( \mathcal{R}(A, k) \) into seat distribution(s) for \((v, h)\).

We now describe each step in detail.

**Step 1.** Given an instance \((v, h)\) of the apportionment problem, we construct an instance \((A, k)\) of the multiwinner election problem as follows. For each \(i \in [p]\), we introduce a set \(C_i\) consisting of \(h\) candidates, and a set \(N_i\) consisting of \(v_i\) voters. Each voter in \(N_i\) approves all candidates in \(C_i\) (and of no other candidates). Furthermore, we define \(C = \bigcup_{i=1}^{p} C_i\), \(N = \bigcup_{i=1}^{p} N_i\), and \(k = h\). Intuitively, \(C_i\) is the set of members of party \(P_i\) and \(N_i\) is the set of voters who voted for party \(P_i\).

**Step 2.** We can now apply multiwinner rule \( \mathcal{R} \) to \((A, k)\) in order to find the set \( \mathcal{R}(A, k) \) of winning committees.

**Step 3.** For every winning committee \( S \in \mathcal{R}(A, k) \), we can extract a seat distribution \( x \) for the instance \((v, h)\) in the following way: the number \(x_i\) of seats of a party \( P_i \) is given by the number of candidates from \( C_i \) in the committee \( S \), i.e., \(x_i = |C_i \cap S|\).

The next example illustrates this three-step procedure.

**Example 1** (Sequential PAV as an apportionment method). Consider the instance \((v, h) = ((20, 40, 30, 10), 10)\) of the apportionment problem. We construct an instance of the multiwinner election setting with 40 candidates; each party \( P_i \) has a set \( C_i \) consisting of 10 candidates. Further, there are \(\sum_{i=1}^{4} v_i = 100\) voters: 20 voters approve the ten candidates in \( C_1 \), 40 voters approve the ten candidates in \( C_2 \), 30 voters the ten candidates in \( C_3 \), and 10 voters the ten candidates in \( C_4 \). The Sequential PAV method selects the winning committee by selecting in 10 consecutive steps candidates from \( C_2, C_3, C_1, C_2, C_3, C_2, C_1, C_2, C_3, C_4 \). Thus, the corresponding seat allocation is \((x_1, x_2, x_3, x_4) = (2, 4, 3, 1)\).

For a given multiwinner rule \( \mathcal{R} \), we let \( M_\mathcal{R} \) denote the apportionment method defined by steps 1 to 3. We say that a multiwinner election rule \( \mathcal{R} \) satisfies (lower) quota if the corresponding apportionment method \( M_\mathcal{R} \) satisfies the respective property.

### 3.1 OWA-Based Apportionment Methods

In this section, we consider apportionment methods induced by OWA-based rules. Fix a weight sequence \( w \) and let \( \mathcal{R} \) denote the \( w \)-based OWA rule. For every instance \((v, h)\) of the apportionment setting, \( M_\mathcal{R}(v, h) \) contains all seat distributions \( x \) maximizing the total voter satisfaction \( u(x) \), which is given by

\[
u(x) = \sum_{i \in [p]} v_i u^w_i(x) = \sum_{i \in [p]} v_i \left( \sum_{j=1}^{x_i} w_j \right).
\]

Here, \( u^w_i(x) = \sum_{j=1}^{x_i} w_j \) denotes the satisfaction of a voter voting for party \( P_i \).

Whenever the weight vector \( w \) is non-increasing, the \( w \)-based OWA rule induces the same apportionment method as its sequential variant.\(^5\)

**Proposition 1.** Let \( w \) be a weight sequence with \( w_j \geq w_{j+1} \geq 0 \) for all \( j \in \mathbb{N} \). The apportionment method induced by the \( w \)-based OWA rule coincides with the apportionment method induced by the sequential \( w \)-based OWA rule.

An immediate corollary is that OWA-based rules with a non-increasing weight sequence can be computed efficiently in the apportionment setting.

Further, we can use Proposition 1 to show that every OWA-based rule with a non-increasing positive weight sequence induces a divisor method. For a weight sequence \( w = (w_1, w_2, \ldots) \), let \( d_w = (d_w(0), d_w(1), \ldots) \) be the sequence defined by \( d_w(s) = \frac{1}{w_{s+1}} \) for all \( s \in \mathbb{N}_0 \). For example, \( w_{PAV} = (1, \frac{1}{2}, \frac{1}{3}, \ldots) \) yields \( d_{PAV} = (1, 2, 3, \ldots) \).

**Theorem 1.** Let \( w \) be a weight sequence such that \( w_j \geq w_{j+1} > 0 \) for all \( j \in \mathbb{N} \). The apportionment method induced by the \( w \)-based OWA rule coincides with the divisor method based on \( d_w = (\frac{1}{w_1}, \frac{1}{w_2}, \frac{1}{w_3}, \ldots) \).

The proof consists in comparing the divisor method based on \( d_w \) with the sequential \( w \)-based OWA rule (which by Proposition 1 coincides with the \( w \)-based OWA in the apportionment setting). In each iteration, the former assigns a seat to a party \( P_i \) maximizing \( \frac{1}{w_{s+1}} \), and the latter assigns a seat to a party maximizing the marginal increase \( \sum_{i \in N} u^w_i(S \cup \{e\}) - u^w_i(S) = v_i w_{s+1} \). Setting \( d_w(s) = \frac{1}{w_{s+1}} \) exactly aligns the two maximization problems.

### 3.2 PAV and the D’Hondt Method

A particularly interesting consequence of Theorem 1 is that Proportional Approval Voting, the OWA rule with \( w_{PAV} = (1, \frac{1}{2}, \frac{1}{3}, \ldots) \), induces the D’Hondt method.

**Corollary 2.** The apportionment method induced by PAV coincides with the D’Hondt method.

The observation that PAV reduces to the D’Hondt method in the party-list setting occasionally occurs (without proof) in the literature (e.g., see Plaza 2004, Pereira 2016, Sánchez-Fernández, Fernández, and Fisteus 2016). \(^6\) Theorem 1 shows that this is just one special case of the general relationship between OWA-based multiwinner rules and divisor methods.

Since the D’Hondt method satisfies lower quota, the same holds for PAV and Sequential PAV.

**Corollary 3.** \( PAV \) and Sequential \( PAV \) satisfy lower quota.

\(^5\)OWA-based rules with non-increasing weight sequences are very natural, especially when viewed in the context of apportionment. OWA-based rules with increasing sequences induce apportionment methods that allocate all seats to the single party that receives the most votes. The same seat distribution can be also obtained by using the OWA-based rule with a constant weight vector (see Proposition 5).

\(^6\)In fact, already Thiele (1895) stated this equivalence, but only in the special case when perfect proportionality is possible; see the survey by Janson (2016).
The fact that PAV satisfies lower quota can also be established by observing that every multiwinner rule satisfying extended justified representation (Aziz et al. 2017) or proportional justified representation (Sánchez-Fernández et al. 2017) also satisfies lower quota; see the full version of this paper for details.

Further, we show that PAV is the only OWA-based rule satisfying lower quota.\footnote{This result also follows from Theorem 1 together with the characterization of the D’Hondt method as the only divisor method satisfying lower quota (Balinski and Young 1982, Proposition 6.4). In the full version of this paper, we give a direct proof.}

**Theorem 2.** PAV is the only OWA-based rule satisfying lower quota.

Theorem 2 characterizes PAV as the only OWA-based rule respecting lower quota. Since PAV does not respect (exact) quota, it follows that no OWA-based rule respects quota.

The load-balancing rule max-Phragmén also induces the D’Hondt method. Indeed, Phragmén formulated his rule as a generalization of the D’Hondt method (Mora and Oliver 2015; Janson 2016).

**Theorem 3.** The apportionment method induced by max-Phragmén coincides with the D’Hondt method.

There is also a sequential variant of Phragmén’s rule (Phragmén 1894).\footnote{In fact, the sequential variant is the main method that Phragmén proposed to be used in actual elections; see the survey by Janson (2016) for details.} It is straightforward to verify that, in the apportionment setting, this variant coincides with max-Phragmén and thus also induces the D’Hondt method.

### 3.3 Phragmén’s Variance-Minimizing Rule and the Sainte-Lagué method

Since the Sainte-Lagué method is the divisor method based on \((1, 3, 5, \ldots, \ldots)\), Theorem 1 implies that it is induced by the \(w\)-based OWA rule with weight sequence \((1, 1/3, 1/5, \ldots)\).\footnote{The fact that the variant of PAV based on weight sequence \((1, 1/3, 1/5, \ldots)\) reduces to the Sainte-Lagué method in the party-list setting is also stated (without proof) by Pereira (2016).}

However, this is not the only multiwinner rule inducing the Sainte-Lagué method. Recall that var-Phragmén is the variant of Phragmén’s load-balancing methods that minimizes the variance of the loads.

**Theorem 4.** The apportionment method induced by var-Phragmén coincides with the Sainte-Lagué method.

The proof consists in observing that, as already Sainte-Lagué (1910) and Owens (1921) have shown, the Sainte-Lagué method selects exactly those seat distributions \(x\) minimizing

\[
\sum_{i \in [p]} v_i \left( \frac{x_i}{v_i} - \frac{h}{v_+} \right)^2
\]

(see also Balinski and Young 1982, pages 103–104). It is not hard to check that the apportionment method induced by var-Phragmén minimizes the same function.

### 3.4 Monroe’s Rule and the Largest Remainder Method

We now turn to Monroe’s multiwinner rule. It turns out that it induces the largest remainder method.

**Theorem 5.** Assume that the number of seats divides the total number of voters. Then, Monroe’s rule induces the largest remainder method.

An immediate consequence of Theorem 5 is that Monroe’s rule respects quota.

### 3.5 Other Multiwinner Rules in the Context of Apportionment

In this section we examine two further OWA-based rules, the Chamberlin–Courant rule and the top-\(k\) rule, in the context of apportionment. Since \(w_{CC} = (1, 0, 0, \ldots)\) and \(w_{\text{top-}k} = (1, \ldots, 1, 0, 0, \ldots)\), Proposition 1 applies to both rules.

The Chamberlin–Courant apportionment method produces lots of ties, because it does not strive to give more than one seat even to parties with a large support. In the special case where the number \(p\) of parties exceeds the number \(h\) of seats, the Chamberlin–Courant rules assigns one seat to each of the \(h\) largest parties.\footnote{In this special case, the apportionment method induced by the Chamberlin–Courant rule coincides with impervious divisor methods (see Footnote 3).}

**Proposition 4.** Consider an instance \((v, h)\) of the apportionment problem. If \(p > h\), the apportionment method induced by the Chamberlin–Courant rule assigns one seat to each of the \(h\) parties with the greatest number of votes.

Proposition 4 gives an interesting insight into the nature of the Chamberlin–Courant apportionment method: it selects an assembly having one representative from each of the \(h\) largest groups of a given society.

The top-\(k\) rule is on the other end of the spectrum of apportionment methods.

**Proposition 5.** The apportionment method induced by the top-\(k\) rule assigns all seats to the party (or parties) receiving the highest number of votes.

Thus, the top-\(k\) rule induces the apportionment method \(M^*\) in Proposition 4.5 of Balinski and Young (1982).

We conclude this section by mentioning two further rules that are often studied in the context of multiwinner elections. **Satisfaction Approval Voting** (Brams and Kilgour 2014) induces the same apportionment methods as the top-\(k\) rule. **And Minimax Approval Voting** (Brams, Kilgour, and Sanver 2007) induces the apportionment method that assigns the seats in a way that maximizes the number of seats of the party with the fewest seats.

### 4 Degressive Proportionality and Election Thresholds

In this section, we show that OWA-based multiwinner rules can also be used to induce apportionment methods with appealing properties other than lower quota. We do this by exploring degressive proportionality, the concept suggesting
that smaller populations should be allocated more representatives in comparison to the divisor methods, and election thresholds, the concept saying that a party should only be represented in parliament if it receives at least a certain numbers of votes. To the best of our knowledge, the OWA-based rules considered in this section have not been studied before.

4.1 Degressive Proportionality

Despite its mathematical elegance and apparent simplicity, the proportionality principle is not always desirable. For instance, in an assembly where decisions are taken under simple majority rule, a cohesive group of 51% has obviously more than a “fair” share. Principles of justice indicate that, for decisions bodies governed by majority rule, fair apportionment should follow a norm of degressive proportionality (Laslier 2012; Koryagin et al. 2013). In fact, degressive apportionment methods can often be observed in parliaments that gather districts, regions, or states of very different sizes, such as the European Parliament.11

The Penrose apportionment method (aka square-root method and devised by Penrose, 1946; see also the work of Słomczyński and Zyczkowski 2006) allocates seats in such a way that the number of seats allocated to a party is proportional to the square root of the votes for that party. It has been proposed for the United Nations Parliamentary Assembly and for allocating voting weights in the Council of the European Union.12

Let us say that an apportionment method $M$ satisfies the Penrose condition if, for every instance $(v, h)$, it holds that $x_i \geq \lfloor \frac{h}{\sum_j \sqrt{v_j}} \rfloor$ for all $i \in [p]$. Interestingly, the Penrose condition can be satisfied by using an OWA-based rule. The weight sequence $w$ achieving this is given by $w_j = \frac{1}{j}$ for all $j \in \mathbb{N}$.

**Theorem 6.** The apportionment method induced by the OWA-based rule with weight sequence $w = (1, \frac{1}{4}, \frac{1}{9}, \ldots)$ satisfies the Penrose condition.

Degressive proportionality is also an important feature of the so-called Cambridge Compromise, which proposes an apportionment method for the European Parliament based on an affine formula: each member state should be endowed with a fixed number (5) of delegates plus a variable number, proportional to the population of the state (Grimmett et al. 2011). We show that such an apportionment method can be implemented via an OWA-based multiwinner rule.

**Proposition 6.** Consider an instance $(v, h)$ of the apportionment setting with $h \geq 5p$ and let $Z$ be a constant with $Z > 5v_1$. Let $R$ denote the $w$-based OWA rule with weight sequence $w = (0, 0, 0, 0, Z, 1/2, 1/3, \ldots)$. Then, for every $x \in M_R(v, h)$ and for every $i \in [p]$, $x_i \geq 5 + \left[ \frac{v_i (h - 5p)}{w_{i+1}} \right]$.

4.2 Election Thresholds

OWA-based multiwinner rules also provide an interesting way for implementing election thresholds. Thresholds in the form of percentage hurdle are often encountered in parliamentary elections (see Pukelsheim 2014, Section 7.6). For a weight sequence $w = (w_1, w_2, \ldots)$, let $w[t]$ be the weight sequence obtained from $w$ by replacing the first $t$ elements of $w$ with zeros. The $w[t]$-based OWA rule induces an apportionment method that allocates seats to a party only if the number of votes the party receives exceeds a certain fraction of the total number of votes received by parties with allocated seats.13 Proposition 7 formalizes this behavior for the weight sequence $w_{PAV}$.

**Proposition 7.** Consider an instance $(v, h)$ of the apportionment problem and fix an integer $t$ with $1 \leq t < h$. Let $R$ denote the OWA-based rule with weight sequence $w_{PAV}[t]$. Then, for all seat distributions $x \in M_R(v, h)$, $x_i > 0$ only if $\frac{v_i}{\sum_{\ell \in [p]} : x_\ell > 0 v_\ell} > \frac{t}{h}$.

5 Conclusion

In legislative procedures, proportional representation is typically achieved by employing party-list apportionment methods such as the D’Hondt method or the largest remainder method. These methods impose proportionality by assuring that each party in a representative body is allocated a number of representatives that is proportional to the number of received votes. Nevertheless, party-list systems have many drawbacks—for instance, they provide very weak links between elected legislators and their constituents.

In this paper we have proposed a simple and natural formal framework that allows us to view approval-based multiwinner election rules as apportionment methods. Some multiwinner rules (such as PAV, Monroe’s rule, Phragmén’s rules, and the rules considered in Section 4) induce apportionment methods that are used—or have been proposed—for parliamentary apportionment. The apportionment methods that are induced by other multiwinner rules (such as the Chamberlin–Courant rule, the top-k rule, Satisfaction Approval Voting, and Minimax Approval Voting) are, however, less appealing. These results give interesting insights into the nature of the analyzed multiwinner rules, and they show how traditional apportionment methods can be extended to settings where voters can vote for individual candidates.

Further, our methodology allowed us to discover a new interesting multiwinner election rule which, if applied to the apportionment setting, satisfies Penrose’s (square root proportionality) condition.

---

11 Even though the composition of the European Parliament is not the result of the application of a well-defined rule, it is interesting to note that the history of successive negotiations produced such a result (see Rose 2013).

12 The problem of allocating voting weights to representatives is formally equivalent to the apportionment problem.
